The $T=0$ dynamical properties of the one-dimensional $s=1$ XXZ model with an additional single-site term are investigated by means of the recursion method. The dynamic structure factors $S_{\mu\lambda}(q=\pi,\omega)$, $\mu=x,z$ bear the characteristic signatures of several different phase transitions. In the $s=1$ Heisenberg antiferromagnet, the intrinsic linewidth (at fixed $q$) of $S_{\mu\lambda}(q,\omega)$ is larger for small $q$ than for $q$ near $\pi$, in contrast to well-established results for the corresponding $s=\frac{1}{2}$ model.

Spin chains with quantum number $s=1$ have been the object of sustained intense study ever since 1983, when Haldane\textsuperscript{1} first predicted the existence of a nonmagnetic phase with an excitation gap for the isotropic Heisenberg antiferromagnet. That research activity has led to a broad consensus on the main features, and many intricate details of the $T=0$ phase diagrams pertaining to several Hamiltonians involving spin-1 chains. The prototype among them is the Heisenberg antiferromagnet with exchange and single-site anisotropies,

\begin{equation}
H = \sum_{\ell=1}^{N} [J(S_{\ell}^{x}S_{\ell+1}^{x} + S_{\ell}^{y}S_{\ell+1}^{y}) + J_{z}S_{\ell}^{z}S_{\ell+1}^{z} + D(S_{\ell}^{z})^{2}] . \tag{1}
\end{equation}

Within the domain $0 \leq J_{x}/J \leq 2$, $0 \leq D/J \leq 2$ considered here for the two anisotropy parameters, a total of four distinct $T=0$ phases have been identified: (i) A Neel phase ($N$) with antiferromagnetic long-range order in $z$ direction is realized for sufficiently large $J_{x}/J$. (ii) A singlet phase ($S$) characterized by a nondegenerate ground state, and an excitation gap exists for large $D/J$. (iii) A critical phase ($C$) with algebraically decaying in-plane correlation function $\langle S_{\ell}^{x}S_{\ell+n}^{x} \rangle$ is present for sufficiently small $J_{z}/J$ and $D/J$. (iv) Contiguous to these three phases is the phase ($H$)—the one first predicted by Haldane. Like ($S$), it is characterized by a nonmagnetic singlet ground state with an excitation gap.\textsuperscript{5} The ground state is critical on the boundaries of ($H$). The ($C/H$) transition is of the Kosterlitz–Thouless type, and the ($N/H$) transition is of the 2D-Ising variety. Both transitions are specified by a single set of critical exponents for the entire phase boundary, except at the endpoints. The critical exponents of the ($S/H$) transition, by contrast, vary continuously along the phase boundary.

What is the characteristic signature of the four phases, and the impact of the three transitions on the $T=0$ dynamic structure factors $S_{\mu\lambda}(q,\omega)$, defined as the Fourier transforms of the space-time correlation functions $\langle S_{\ell}^{\mu}(t)S_{\ell+n}^{\lambda} \rangle$, $\mu=x,z$? The first goal of this study is to investigate this important question with an application of the recursion method. The second goal will be a study of line shapes of $S_{\mu\lambda}(q,\omega)$ for an experimentally relevant situation.

The recursion method, which, in the present context, is based on an orthogonal expansion of the wave function $\langle \phi_{0}(t) \rangle = S_{\mu}(\omega) \langle \phi_{0} \rangle$, $S_{\mu} = e^{-i\Omega_{\mu}(\omega)}$, yields (after several intermediate steps)$^6$ a sequence of continued-fraction coefficients $\Delta_{1}^{\mu}(q), \Delta_{2}^{\mu}(q), \ldots$, for the relaxation function,

\begin{equation}
c_{0}^{\mu}(q,z) = \frac{1}{z + \Delta_{1}^{\mu}(q)} , \tag{2}
\end{equation}

from which the $T=0$ dynamic structure factor can be inferred as

\begin{equation}
S_{\mu\lambda}(q,\omega) = 4 \langle S_{\lambda}^{\mu}(q) \rangle \Theta(\omega) \lim_{\epsilon \to 0} \Re [c_{0}^{\mu}(q,\epsilon - i\omega)] . \tag{3}
\end{equation}

The finite-size ground-state wave function $\langle \phi_{0} \rangle$ must be computed up front. We use the conjugate-gradient method for that task.\textsuperscript{9}

Despite the nontrivial $N$ dependence of $\langle \phi_{0} \rangle$ in the present application, the first $K=N/2$ coefficients $\Delta_{k}^{\mu}(q), \ldots, \Delta_{K}^{\mu}(q)$ are, at most, weakly size dependent. They reflect key properties of $S_{\mu\lambda}(q,\omega)$ for the infinite system more faithfully than the subsequent coefficients, which depend strongly on $N$. Our continued-fraction analysis uses the nearly size-independent coefficients (i) for the detection of dynamically relevant excitation gaps and (ii) for the determination of the spectral-weight distribution in $S_{\mu\lambda}(q,\omega)$.

As is typical in quantum many-body dynamics, the nearly size-independent sequences $\Delta_{k}^{\mu}(q), k=1,\ldots,K$, obtained here grow linearly with $k$, on average, and exhibit one or several patterns that translate into specific properties of $S_{\mu\lambda}(q,\omega)$ related to the type of ordering, the presence of excitation gaps, the size of bandwidths, and the exponents of infrared singularities. The techniques of analysis for these properties have been described in previous or concurrent applications.

\textsuperscript{a) On leave from the Institut f"{u}r Physik, Universit"{a}t Dortmund, 44221 Dortmund, Germany.}
plotted the $J, J\parallel J$ dependence for fixed $D/J = 0$ of the excitation gaps for operators $S_{\pi}^z$ (circles) and $S_{\pi}^x$ (squares). At $J/J = 0$, our analysis yields a gap of size $b_{1,\pi}$ which is dynamically relevant for the operators involving the matching of the nearly size-independent coefficients $\Delta_{\mu}^{\pi}(\Omega)$, $k = 1, \ldots, K$, computed by means of the recursion method from the $N=12$ ground-state wave function. The vertical arrows indicate the locations where the three lines in parameter space cross phase boundaries.

For the second line in parameter space [see Fig. 1(b)], we keep the exchange parameter fixed at $J/J = 1$ and vary the single-site parameter $D/J$. At $D/J = 0$, which is equivalent to the midpoint of line (a), the $S_{\pi}^z$ gap starts out nonzero and grows with increasing $D/J$, which reflects the fact that low-frequency out-of-plane fluctuations are more and more suppressed as the easy-plane anisotropy becomes stronger. The $S_{\pi}^x$ gap, by contrast, has a decreasing trend. Starting from the same value at $D/J = 0$, it reaches a minimum near zero at $D/J = 0.15$ and then grows again. The minimum marks the $(H/S)$ transition between two nonmagnetic phases, where only the staggered in-plane fluctuations become critical.

Now we shift the line $0 \leq D/J \leq 2$ in parameter space from $J/J = 1$ [Fig. 1(b)] to $J/J = 1.5$ [Fig. 1(c)]. At $D/J = 0$ the system is in the Néel phase. Here the $S_{\pi}^z$ gap is large, reflecting the transverse spin waves of a uniaxial antiferromagnet, whereas the $S_{\pi}^x$ gap is effectively zero, reflecting the twofold degeneracy of the ground state associated with antiferromagnetic ordering. As $D/J$ increases from zero, the $S_{\pi}^x$ gap stays near zero up to the $(N/H)$ phase boundary at $D/J = 0.5$, where it starts to increase very rapidly with no further change in course. The $S_{\pi}^z$ gap decreases from some large value as $D/J$ increases from zero. It goes through a minimum near zero at $D/J = 1.7$, marking, as in Fig. 1(b), the $(H/S)$ transition, now shifted to a higher value of single-site anisotropy, in agreement with the broadly accepted picture.

The significance of the results displayed in Fig. 1 is that they have been derived entirely from the ground-state wave function of a chain with just $N=12$ spins. It is certainly surprising that the spectral signatures of the rather complex phase diagram are so clearly encoded in that quantity and that this information is so easily retrievable.

The same type of gap analysis carried out for the $q$ dependence of the operator $S_{\mu}^x$ yields the dispersion of the lowest branch of excitations which is dynamically relevant for $S_{\mu}^x(q, \omega)$. Toward our second goal we reconstruct the dynamic structure factor itself via (3) from expression (2) with coefficients $\Delta_{\mu}^{x}(q)$, $\Delta_{\mu}^{y}(q)$, and a termination function tailored, such as to extrapolate the recognizable pattern of the first $K$ coefficients. A detailed account of the reconstruction has been reported in Ref. 8. Here we must limit the discussion to a couple of specific issues: What is the main difference in line shape between the functions $S_{\mu}^x(q, \omega)$ of the $s=1$ Heisenberg antiferromagnet and its $s=1/2$ counterpart, and what is the impact of a small easy-plane single-site anisotropy on the peak positions and line shapes in the $s=1$ case?

Figure 2(a) shows the reconstructed (normalized) dynamic structure factor $S_{\mu}^x(q, \omega) = S_{\mu}^x(q, \omega)/(S_{\mu}^{xx}(q))$ at $q = \pi/6$ and $q = 5\pi/6$ for the 1D $s=1$ Heisenberg antiferromagnet. For both wave numbers, the function consists of a single peak with nonzero intrinsic linewidth. This is in strong contrast to the results obtained from truncated continued fractions or equivalent procedures, which are sums of $\delta$ functions, often broadened into Lorentzians for graphical representation.

We note two main differences between the results of Fig.
We show results for (a) the $s = 1$ Heisenberg antiferromagnet and (b) the same model with an additional easy-plane single-site anisotropy, $D/J = 0.18$. We observe for $\mu = s_z$ and $q = \pi/6$, $5\pi/6$. They have been derived from $K = 6$ continued fraction coefficients $\Delta^k_p(q), k = 1, \ldots, K$ extracted from the $N = 12$ ground-state wave function combined with the continued-fraction analysis described in Ref. 8. The arrow near the peak of each curve indicates the energy of the lowest excitation with nonzero matrix element in $S_{\mu\nu}(q,\omega)$ of the $N = 12$ chain.

Fig. 2. Normalized dynamic structure factor $S_{\mu\nu}(q,\omega)/S_{\mu\nu}(\omega)$ at $T = 0$ of (a) the 1D $s = 1$ Heisenberg antiferromagnet and (b) the same model with an additional easy-plane single-site anisotropy, $D/J = 0.18$. We show results for $\mu = s_z$, and $q = \pi/6$, $5\pi/6$. They have been derived from $K = 6$ continued fraction coefficients $\Delta^k_p(q), k = 1, \ldots, K$ extracted from the $N = 12$ ground-state wave function combined with the continued-fraction analysis described in Ref. 8. The arrow near the peak of each curve indicates the energy of the lowest excitation with nonzero matrix element in $S_{\mu\nu}(q,\omega)$ of the $N = 12$ chain.

2(a) and the corresponding results of the $s = \frac{1}{2}$ model (see Ref. 8): (a) the peak positions at wave numbers $q$ and $\pi - q$ are the same for $s = \frac{1}{2}$ but differ substantially for $s = 1$. The symmetric dispersion of the $s = \frac{1}{2}$ chain is exactly known, and the asymmetric dispersion of the $s = 1$ chain has been well established by extensive numerical diagonalizations.11,12 (b) The linewidth is known to increase monotonically with increasing $q$ in the $s = \frac{1}{2}$ case,8,13 but in Fig. 2(a) the $s = 1$ result at small $q$ has a considerably larger linewidth than the one at $q$ near $\pi$. Our $s = 1$ results are consistent with the findings of Refs. 11 and 12 that the spectral weight in $S_{\mu\nu}(q,\omega)$ is dominated by a single $\delta$ function at $q$ near $\pi$, but less so at small $q$. The opposite trends of line broadening in the $s = \frac{1}{2}$ and $s = 1$ chains may be understood by interpreting the observable excitations as composites of different kinds of elementary states.

The presence of some easy-plane anisotropy, $D/J = 0.18$, alters the functions $S_{\mu\nu}(\pi/6,\omega)$ and $S_{\mu\nu}(5\pi/6,\omega)$, as shown in Fig. 2(b). In-plane ($xx$) and out-of-plane ($zz$) fluctuations are now represented by separate peaks. At small $q$, the in-plane peak has moved up and the out-of-plane peak down. At small $\pi - q$, they have moved in opposite directions. the anisotropy causes an increase in in-plane line-widths. The peak positions of the reconstructed functions $S_{\mu\nu}(5\pi/6,\omega)$ shown in Fig. 2 are in good agreement with the energies of the lowest-lying dynamically relevant excitation of a chain with $N = 12$ spins. The latter, quoted from Ref. 12, are indicated by arrows in Fig. 2. However, for $q = \pi/6$ the peaks lie significantly higher than the lowest $N = 12$ excitation.

The significance of the point $(J_2/J = 1, D/J = 0.18)$ in the parameter space of Hamiltonian (1) is its physical realization by the quasi-1D magnetic compound Ni(C1,W8N2)2NO3ClO4 (NENP). A recent inelastic neutron scattering study on that compound14 observes well-defined resonances for $0.3\pi < q < \pi$, including $q = 5\pi/6$, where our result predicts a peak with small but nonzero linewidth. At smaller wave numbers including $q = \pi/6$, the resonance in the experiment has disappeared in a broad background intensity. Here our analysis predicts a broad signal, which, when multiplied by the very small integrated intensity, becomes indeed undetectable for all practical purposes.
